# Notes for 'Thinking with Types: Type-level Programming in Haskell', Chapter 1–5

✎ March 18, 2020

🕐 A fifteen minute read

❧ Tags: haskell, notes, programming

Haskell — with its powerful type system — has a great support for type-level programming and it has gotten much better in the recent times with the new releases of the GHC compiler. But type-level programming remains a daunting topic even with seasoned haskellers. *Thinking with Types: Type-level Programming in Haskell* by Sandy Maguire is a book which attempts to fix that. I've taken some notes to summarize my understanding of the same.

## Contents

## Introduction

- Type-level Programming (TLP) is writing programs that run at compile-time, unlike term-level programming which is writing programs that run at run-time.
- TLP should be used in moderation.
- TLP should be mostly used
    - for programs that are catastrophic to get wrong (finance, healthcare, etc).
    - when it simplifies the program API massively.
    - when power-to-weight ratio of adding TLP is high.

- Types are not a silver bullet for fixing all errors:
  - Correct programs can be not well-typed.
  - It could be hard to assign type for useful programs. e.g. `printf` from C.
- Types can turn possible runtime errors into compile-time errors.

# Chapter 1. The Algebra Behind Types

## Isomorphisms and Cardinalities

- *Cardinality* of a type is the number of values it can have ignoring bottoms. The values of a type are also called the *inhabitants* of the type.

```
1  data Void
2   -- no possible values. cardinality: 0
3  data Unit = Unit
4   -- only one possible value. cardinality: 1
5  data Bool = True | False
6   -- only two possible values. cardinality: 2
```

- Cardinality is written using notation: `|Void| = 0`
- Two types are said to be *Isomorphic* if they have same cardinality.
- An *isomorphism* between types a and b is a pair of functions `to` and `from` such that:

```
1  to :: a -> b
2  from :: b -> a
3  to . from = id
4  from . to = id
```

## Sum, Product and Exponential Types

- `Either a b` is a *Sum* type. Its number of inhabitants is sum of the number of inhabitants of type a and b like so: `|a|` possible values with `Left` constructor and `|b|` possible values with the `Right` constructor. Formally:

```
1  |Either a b| = |a| + |b|
```

- `(a, b)` is a *Product* type. Its number of inhabitant is the product of the number of inhabitants of types a and b. Formally:

```
1  |(a, b)| = |a| * |b|
```

- Some more examples:

```
1  |Maybe a| = |Nothing| + |Just a| = 1 + |a|
2  |[a]| = 1 + |a| + |a|^2 + |a|^3 + ...
3  |Either a Void| = |a| + 0 = |a|
4  |Either Void a| = 0 + |a| = |a|
5  |(a, Unit)| = |a| * 1 = |a|
6  |(Unit, a)| = 1 * |a| = |a|
```

‣ Function types are exponentiation types.

```
1  |a -> b| = |b|^|a|
```

For every value in domain a there can be `|b|` possible values in the range b. And there are `|a|` possible values in domain a. So:

```
1  |a -> b|
2    = |b| * |b| * ... * |b| -- (|a| times)
3    = |b|^|a|
```

‣ Data can be represented in many possible isomorphic types. Some of them are more useful than others. Example:

```haskell
data TicTacToe1 a = TicTacToe1
  { topLeft      :: a
  , topCenter    :: a
  , topRight     :: a
  , middleLeft   :: a
  , middleCenter :: a
  , middleRight  :: a
  , bottomLeft   :: a
  , bottomCenter :: a
  , bottomRight  :: a
  }

|TicTacToe1 a|
  = |a| * |a| * ... * |a| -- 9 times
  = |a|^9

emptyBoard1 :: TicTacToe1 (Maybe Bool)
emptyBoard1 =
  TicTacToe1 Nothing Nothing Nothing
             Nothing Nothing Nothing
             Nothing Nothing Nothing

-- Alternatively

data Three = One | Two | Three
data TicTacToe2 a =
  TicTacToe2 (Three -> Three -> a)

|TicTacToe2 a| = |a|^(|Three| * |Three|)
               = |a|^(3*3)
               = |a|^9

emptyBoard2 :: TicTacToe2 (Maybe Bool)
emptyBoard2 =
  TicTacToe2 $ const $ const Nothing
```

## The Curry-Howard Isomorphism

- Every logic statement can be expressed as an equivalent computer program.
- Helps us analyze mathematical theorems through programming.

## Canonical Representations

- Since multiple equivalent representations of a type are possible, the representation in form of sum of products is considered the canonical representation of the type. Example:

```
1  Either a (Either b (c, d)) -- canonical
2
3  (a, Bool) -- not canonical
4  Either a a
5  -- same cardinality as above but canonical
```

# Chapter 2. Terms, Types and Kinds

## The Kind System

- *Terms* are things manipulated at runtime. *Types* of terms are used by compiler to prove "things" about the terms.
- Similarly, *Types* are things manipulated at compile-time. *Kinds* of types are used by the compiler to prove "things" about the types.
- Kinds are "the types of the Types".
- Kind of things that can exist at runtime (terms) is `*`. That is, kind of `Int`, `String` etc is `*`.

```
1  > :type True
2  True :: Bool
3  > :kind Bool
4  Bool :: *
```

- There are kinds other than `*`. For example:

```
1  > :kind Show Int
2  Show Int :: Constraint
```

- Higher-kinded types have (`->`) in their kind signature:

```
1   > :kind Maybe
2   Maybe :: * -> *
3   > :kind Maybe Int
4   Maybe Int :: *
5
6   > :type Control.Monad.Trans.Maybe.MaybeT
7   Control.Monad.Trans.Maybe.MaybeT
8     :: m (Maybe a) -> Control.Monad.Trans.Maybe.MaybeT m a
9   > :kind Control.Monad.Trans.Maybe.MaybeT
10  Control.Monad.Trans.Maybe.MaybeT :: (* -> *) -> * -> *
11  > :kind Control.Monad.Trans.Maybe.MaybeT IO Int
12  Control.Monad.Trans.Maybe.MaybeT IO Int :: *
```

## Data Kinds

- `-XDataKinds` extension lets us create new kinds.
- It lifts data constructors into type constructors and types into kinds.

```
1  > :set -XDataKinds
2  > data Allow = Yes | No
3  > :type Yes
4  Yes :: Allow
5  -- Yes is data constructor
6  > :kind Allow -- Allow is a type
7  Allow :: *
8  > :kind 'Yes
9  'Yes :: Allow
10 -- 'Yes is a type too. Its kind is 'Allow.
```

▸ Lifted constructors and types are written with a preceding ' (called *tick* ).

## Promotion of Built-In Types

▸ `-XDataKinds` extension promotes built-in types too.
▸ Strings are promoted to the kind `Symbol`.
▸ Natural numbers are promoted to the kind `Nat`.

```
1  > :kind "hi"
2  "hi" :: GHC.Types.Symbol
3  -- "hi" is a type-level string
4  > :kind 123
5  123 :: GHC.Types.Nat
6  -- 123 is a type-level natural number
```

▸ We can do type level operations on `Symbols` and `Nats`.

```
1  > :m +GHC.TypeLits
2  GHC.TypeLits> :kind AppendSymbol
3  AppendSymbol :: Symbol -> Symbol -> Symbol
4  GHC.TypeLits> :kind! AppendSymbol "hello " "there"
5  AppendSymbol "hello " "there" :: Symbol
6  = "hello there"
7  GHC.TypeLits> :set -XTypeOperators
8  GHC.TypeLits> :kind! (1 + 2) ^ 7
9  (1 + 2) ^ 7 :: Nat
10 = 2187
```

▸ `-XTypeOperators` extension is needed for applying type-level functions with symbolic identifiers.
▸ There are type-level lists and tuples:

```
1   GHC.TypeLits> :kind '[ 'True ]
2   '[ 'True ] :: [Bool]
3   GHC.TypeLits> :kind '[1,2,3]
4   '[1,2,3] :: [Nat]
5   GHC.TypeLits> :kind '["abc"]
6   '["abc"] :: [Symbol]
7   GHC.TypeLits> :kind 'False ': 'True ': '[]
8   'False ': 'True ': '[] :: [Bool]
9   GHC.TypeLits> :kind '(6, "x", 'False)
10  '(6, "x", 'False) :: (Nat, Symbol, Bool)
```

## Type-level Functions

▸ With the `-XTypeFamilies` extension, it's possible to write new type-level functions as closed type families:

```
1   > :set -XDataKinds
2   > :set -XTypeFamilies
3   > :{
4   | type family And (x :: Bool) (y :: Bool) :: Bool where
5   |   And 'True 'True = 'True
6   |   And _     _     = 'False
7   | :}
8   > :kind And
9   And :: Bool -> Bool -> Bool
10  > :kind! And 'True 'False
11  And 'True 'False :: Bool
12  = 'False
13  > :kind! And 'True 'True
14  And 'True 'True :: Bool
15  = 'True
16  > :kind! And 'False 'True
17  And 'False 'True :: Bool
18  = 'False
```

# Chapter 3. Variance

▸ There are three types of *Variance* (`T` here a type of kind `* -> *`):
  ▸ Covariant: any function of type `a -> b` can be lifted into a function of type `T a -> T b`.
    Covariant types are instances of the `Functor` typeclass:

```
class Functor f where
  fmap :: (a -> b) -> f a -> f b
```

  ▸ Contravariant: any function of type `a -> b` can be lifted into a function of type `T b -> T a`.
    Contravariant functions are instances of the `Contravariant` typeclass:

```
class Contravariant f where
  contramap :: (a -> b) -> f b -> f a
```

  ▸ Invariant: no function of type `a -> b` can be lifted into a function of type `T a`. Invariant
    functions are instances of the `Invariant` typeclass:

```
class Invariant f where
  invmap :: (a -> b) -> (b -> a) -> f a -> f b
```

▸ Variance of a type `T` is specified with respect to a particular type parameter. A type `T` with two
  parameters a and `b` could be covariant wrt. a and contravariant wrt. `b`.
▸ Variance of a type `T` wrt. a particular type parameter is determined by whether the parameter
  appears in positive or negative *position*s.
  ▸ If a type parameter appears on the left-hand side of a function, it is said to be in a negative
    position. Else it is said to be in a positive position.
  ▸ If a type parameter appears only in positive positions then the type is covariant wrt. that
    parameter.
  ▸ If a type parameter appears only in negative positions then the type is contravariant wrt. that
    parameter.
  ▸ If a type parameter appears in both positive and negative positions then the type is invariant
    wrt. that parameter.
  ▸ positions follow the laws of multiplication for their *sign*s.

| a | b | a * b |
|---|---|---|
| + | + | + |
| + | - | - |
| - | + | - |
| - | - | + |

▸ Examples:

```haskell
1   newtype T1 a = T1 (Int -> a)
2   -- a is in +ve position, T1 is covariant wrt. a.
3   newtype T2 a = T2 (a -> Int)
4   -- a is in -ve position, T2 is contravariant wrt. a.
5   newtype T3 a = T3 (a -> a)
6   -- a is in both -ve and +ve position. T3 is invariant wrt. a.
7   newtype T4 a = T4 ((Int -> a) -> Int)
8   -- a is in +ve position but (Int -> a) is in -ve position.
9   -- So a is in -ve position overall. T4 is contravariant wrt. a.
10  newtype T5 a = T5 ((a -> Int) -> Int)
11  -- a is in -ve position but (a -> Int) is in -ve position.
12  -- So a is in +ve position overall. T5 is covariant wrt. a.
```

- ▸ Covariant parameters are said to be *produced* or *owned* by the type.
- ▸ Contravariant parameters are said to be *consumed* by the type.
- ▸ A type that has two parameters and is covariant in both of them is an instance of `BiFunctor`.
- ▸ A type that has two parameters and is contravariant in first parameter and covariant in second parameter is an instance of `Profunctor`.

# Chapter 4. Working with Types

- ▸ Standard Haskell has no notion of scopes for types.
- ▸ `-XScopedTypeVariables` extension lets us bind type variables to a scope. It requires an explicitly `forall` quantifier in type signatures.

```
1   -- This does not compile.
2   > :{
3   | comp :: (a -> b) -> (b -> c) -> a -> c
4   | comp f g a = go f
5   |   where
6   |     go :: (a -> b) -> c
7   |     go f' = g (f' a)
8   | :}
9
10  <interactive>:11:11: error:
11      • Couldn't match expected type 'c1' with actual type 'c'
12        'c1' is a rigid type variable bound by
13          the type signature for:
14            go :: forall a1 b1 c1. (a1 -> b1) -> c1
15          at <interactive>:10:3-21
16        'c' is a rigid type variable bound by
17          the type signature for:
18            comp :: forall a b c. (a -> b) -> (b -> c) -> a -> c
19          at <interactive>:7:1-38
20      • In the expression: g (f' a)
21
22  <interactive>:11:14: error:
23      • Couldn't match expected type 'b' with actual type 'b1'
24        'b1' is a rigid type variable bound by
25          the type signature for:
26            go :: forall a1 b1 c1. (a1 -> b1) -> c1
27          at <interactive>:10:3-21
28        'b' is a rigid type variable bound by
29          the type signature for:
30            comp :: forall a b c. (a -> b) -> (b -> c) -> a -> c
31          at <interactive>:7:1-38
32      • In the first argument of 'g', namely '(f' a)'
33
34  <interactive>:11:17: error:
35      • Couldn't match expected type 'a1' with actual type 'a'
36        'a1' is a rigid type variable bound by
37          the type signature for:
38            go :: forall a1 b1 c1. (a1 -> b1) -> c1
39          at <interactive>:10:3-21
40        'a' is a rigid type variable bound by
41          the type signature for:
42            comp :: forall a b c. (a -> b) -> (b -> c) -> a -> c
43          at <interactive>:7:1-38
44      • In the first argument of 'f'', namely 'a'
45
46  -- But this does.
47  > :set -XScopedTypeVariables
48  > :{
49  | comp :: forall a b c. (a -> b) -> (b -> c) -> a -> c
50  | comp f g a = go f
```

```
51 |   where
52 |     go :: (a -> b) -> c
53 |     go f' = g (f' a)
54 |  :}
```

▸ `-XTypeApplications` extension lets us directly apply types to expressions:

```
1  > :set -XTypeApplications
2  > :type traverse
3  traverse
4    :: (Traversable t, Applicative f) =>
5       (a -> f b) -> t a -> f (t b)
6  > :type traverse @Maybe
7  traverse @Maybe
8    :: Applicative f =>
9       (a -> f b) -> Maybe a -> f (Maybe b)
10 > :type traverse @Maybe @[]
11 traverse @Maybe @[]
12   :: (a -> [b]) -> Maybe a -> [Maybe b]
13 > :type traverse @Maybe @[] @Int
14 traverse @Maybe @[] @Int
15   :: (Int -> [b]) -> Maybe Int -> [Maybe b]
16 > :type traverse @Maybe @[] @Int @String
17 traverse @Maybe @[] @Int @String
18   :: (Int -> [String]) -> Maybe Int -> [Maybe String]
```

▸ Types are applied in the order they appear in the type signature. It is possible to avoid applying types by using a type with an underscore: `@_`

```
1  > :type traverse @Maybe @_ @_ @String
2  traverse @Maybe @_ @_ @String
3    :: Applicative w1 =>
4       (w2 -> w1 String) -> Maybe w2 -> w1 (Maybe String)
```

▸ Sometimes the compiler cannot infer the type of an expression. `-XAllowAmbiguousTypes` extension allow such programs to compile.

```
1  > :set -XScopedTypeVariables
2  > :{
3  | f :: forall a. Show a => Bool
4  | f = True
5  | :}
6
7  <interactive>:7:6: error:
8      • Could not deduce (Show a0)
9        from the context: Show a
10         bound by the type signature for:
11                    f :: forall a. Show a => Bool
12         at <interactive>:7:6-29
13        The type variable 'a0' is ambiguous
14      • In the ambiguity check for 'f'
15        To defer the ambiguity check to use sites, enable AllowAmbiguousTypes
16        In the type signature: f :: forall a. Show a => Bool
```

▸ `Proxy` is a type isomorphic to `()` except with a phantom type parameter:

```
1  data Proxy a = Proxy
```

▸ With all the three extensions enabled, it is possible to get a term-level representation of types using the `Data.Typeable` module:

```
1  > :set -XScopedTypeVariables
2  > :set -XTypeApplications
3  > :set -XAllowAmbiguousTypes
4  > :m +Data.Typeable
5  Data.Typeable> :{
6  Data.Typeable| typeName :: forall a. Typeable a => String
7  Data.Typeable| typeName = show . typeRep $ Proxy @a
8  Data.Typeable| :}
9  Data.Typeable> typeName @String
10 "[Char]"
11 Data.Typeable> typeName @(IO Int)
12 "IO Int"
```

# Chapter 5. Constraints and GADTs

## Constraints

▸ *Constraints* are a kind different than the types (*).
▸ Constraints are what appear on the left-hand side on the fat context arrow =>, like `Show a`.

```
1  > :k Show
2  Show :: * -> Constraint
3  > :k Show Int
4  Show Int :: Constraint
5  > :k (Show Int, Eq String)
6  (Show Int, Eq String) :: Constraint
```

- ‣ Type equalities (`Int ~ a`) are another way of creating Constraints. (`Int ~ a`) says a is same as `Int`.
- ‣ Type equalities are
  - ‣ reflexive: a ~ a always
  - ‣ symmetrical: a ~ b implies b ~ a
  - ‣ transitive: a ~ b and b ~ c implies a ~ c

## GADTs

- ‣ *GADTs* are Generalized Algebraic DataTypes. They allow writing explicit type signatures for data constructors. Here is the code for a length-typed list using GADTs:

```
1   > :set -XGADTs
2   > :set -XKindSignatures
3   > :set -XTypeOperators
4   > :set -XDataKinds
5   > :m +GHC.TypeLits
6   GHC.TypeLits> :{
7   GHC.TypeLits| data List (a :: *) (n :: Nat) where
8   GHC.TypeLits|   Nil  :: List a 0
9   GHC.TypeLits|   (:~) :: a -> List a n -> List a (n + 1)
10  GHC.TypeLits| infixr 5 :~
11  GHC.TypeLits| :}
12  GHC.TypeLits> :type Nil
13  Nil :: List a 0
14  GHC.TypeLits> :type 'a' :~ Nil
15  'a' :~ Nil :: List Char 1
16  GHC.TypeLits> :type 'b' :~ 'a' :~ Nil
17  'b' :~ 'a' :~ Nil :: List Char 2
18  GHC.TypeLits> :type True :~ 'a' :~ Nil
19
20  <interactive>:1:9: error:
21      • Couldn't match type 'Char' with 'Bool'
22        Expected type: List Bool 1
23          Actual type: List Char (0 + 1)
24      • In the second argument of '(:~)', namely ''a' :~ Nil'
25        In the expression: True :~ 'a' :~ Nil
```

- ‣ GADTs are just syntactic sugar for ADTs with type equalities. The above definition is equivalent to:

```
1   > :set -XGADTs
2   > :set -XKindSignatures
3   > :set -XTypeOperators
4   > :set -XDataKinds
5   > :m +GHC.TypeLits
6   GHC.TypeLits> :{
7   GHC.TypeLits| data List (a :: *) (n :: Nat)
8   GHC.TypeLits|   = (n ~ 0) => Nil
9   GHC.TypeLits|   | a :~ List a (n - 1)
10  GHC.TypeLits| infixr 5 :~
11  GHC.TypeLits| :}
12  GHC.TypeLits> :type 'a' :~ Nil
13  'a' :~ Nil :: List Char 1
14  GHC.TypeLits> :type 'b' :~ 'a' :~ Nil
15  'b' :~ 'a' :~ Nil :: List Char 2
```

▸ Type-safety of this list can be used to write a safe `head` function which does not compile for an empty list:

```
1   GHC.TypeLits> :{
2   GHC.TypeLits| safeHead :: List a (n + 1) -> a
3   GHC.TypeLits| safeHead (x :~ _) = x
4   GHC.TypeLits| :}
5   GHC.TypeLits> safeHead ('a' :~ 'b' :~ Nil)
6   'a'
7   GHC.TypeLits> safeHead Nil
8
9   <interactive>:21:10: error:
10      • Couldn't match type '1' with '0'
11        Expected type: List a (0 + 1)
12          Actual type: List a 0
13      • In the first argument of 'safeHead', namely 'Nil'
14        In the expression: safeHead Nil
15        In an equation for 'it': it = safeHead Nil
```

## Heterogeneous Lists

We can use GADTs to build heterogeneous lists which can store values of different types and are type-safe to use.[1]

First, the required extensions and imports:

```
1   {-# LANGUAGE KindSignatures #-}
2   {-# LANGUAGE DataKinds #-}
3   {-# LANGUAGE TypeOperators #-}
4   {-# LANGUAGE GADTs #-}
5   {-# LANGUAGE FlexibleInstances #-}
6   {-# LANGUAGE FlexibleContexts #-}
7   {-# LANGUAGE TypeApplications #-}
8   {-# LANGUAGE ScopedTypeVariables #-}
9
10  module HList where
11
12  import Data.Typeable
```

HList is defined as a GADT:

```
1   data HList (ts :: [*]) where
2     HNil :: HList '[]
3     (:#) :: t -> HList ts -> HList (t ': ts)
4   infixr 5 :#
```

Example usage:

```
1   *HList> :type HNil
2   HNil :: HList '[]
3   *HList> :type 'a' :# HNil
4   'a' :# HNil :: HList '[Char]
5   *HList> :type True :# 'a' :# HNil
6   True :# 'a' :# HNil :: HList '[Bool, Char]
```

We can write operations on HList:

```
1   hLength :: HList ts -> Int
2   hLength HNil = 0
3   hLength (x :# xs) = 1 + hLength xs
4
5   hHead :: HList (t ': ts) -> t
6   hHead (t :# _) = t
```

Example usage:

```
1   *HList> hLength $ True :# 'a' :# HNil
2   2
3   *HList> hHead $ True :# 'a' :# HNil
4   True
5   *HList> hHead HNil
6
7   <interactive>:7:7: error:
8       • Couldn't match type ''[]' with 't : ts0'
9         Expected type: HList (t : ts0)
10          Actual type: HList '[]
11      • In the first argument of 'hHead', namely 'HNil'
12        In the expression: hHead HNil
13        In an equation for 'it': it = hHead HNil
14      • Relevant bindings include it :: t (bound at <interactive>:7:1)
```

We need to define instances of typeclasses like `Eq`, `Ord` etc. for `HList` because GHC cannot derive them automatically yet:

```
1   instance Eq (HList '[]) where
2     HNil == HNil = True
3   instance (Eq t, Eq (HList ts))
4       => Eq (HList (t ': ts)) where
5     (x :# xs) == (y :# ys) =
6       x == y && xs == ys
7
8   instance Ord (HList '[]) where
9     HNil `compare` HNil = EQ
10  instance (Ord t, Ord (HList ts))
11      => Ord (HList (t ': ts)) where
12    (x :# xs) `compare` (y :# ys) =
13      x `compare` y <> xs `compare` ys
14
15  instance Show (HList '[]) where
16    show HNil = "[]"
17  instance (Typeable t, Show t, Show (HList ts))
18      => Show (HList (t ': ts)) where
19    show (x :# xs) =
20      show x
21      ++ "@" ++ show (typeRep (Proxy @t))
22      ++ " :# " ++ show xs
```

The instances are defined recursively: one for the base case and one for the inductive case.

Example usage:

```
1  *HList> True :# 'a' :# HNil == True :# 'a' :# HNil
2  True
3  *HList> True :# 'a' :# HNil == True :# 'b' :# HNil
4  False
5  *HList> True :# 'a' :# HNil == True :# HNil
6
7  <interactive>:17:24: error:
8      • Couldn't match type ''[]' with ''[Char]'
9        Expected type: HList '[Bool, Char]
10          Actual type: HList '[Bool]
11      • In the second argument of '(==)', namely 'True :# HNil'
12        In the expression: True :# 'a' :# HNil == True :# HNil
13        In an equation for 'it': it = True :# 'a' :# HNil == True :# HNil
14 *HList> show $ True :# 'a' :# HNil
15 "True@Bool :# 'a'@Char :# []"
```

## Creating New Constraints

▸ Type families can be used to create new Constraints:

```
1  > :set -XKindSignatures
2  > :set -XDataKinds
3  > :set -XTypeOperators
4  > :set -XTypeFamilies
5  > :m +Data.Constraint
6  Data.Constraint> :{
7  Data.Constraint| type family AllEq (ts :: [*]) :: Constraint where
8  Data.Constraint|   AllEq '[] = ()
9  Data.Constraint|   AllEq (t ': ts) = (Eq t, AllEq ts)
10 Data.Constraint| :}
11 Data.Constraint> :kind! AllEq '[Bool, Char]
12 AllEq '[Bool, Char] :: Constraint
13 = (Eq Bool, (Eq Char, () :: Constraint))
```

▸ `AllEq` is a type-level function from a list of types to a constraint.
▸ With the `-XConstraintKinds` extension, `AllEq` can be made polymorphic over all constraints instead of just `Eq`:

```
1  > :set -XConstraintKinds
2  Data.Constraint> :{
3  Data.Constraint| type family All (c :: * -> Constraint)
4  Data.Constraint|                 (ts :: [*]) :: Constraint where
5  Data.Constraint|   All c '[] = ()
6  Data.Constraint|   All c (t ': ts) = (c t, All c ts)
7  Data.Constraint| :}
```

▸ With `All`, instances for `HList` can be written non-recursively:

```haskell
instance All Eq ts => Eq (HList ts) where
  HNil == HNil = True
  (a :# as) == (b :# bs) = a == b && as == bs
```
